ABSTRACT

Objective: Appendicitis is a common surgical emergency among children. The coronavirus pandemic affected the system of hospitals more than any other field, and great amount of people were concerned about visiting the hospitals for any reason. In this study, it was aimed to evaluate the profile of appendicitis by emphasizing perforated and acute appendicitis in the pandemic period and to compare the rates with previous three years.

Material and Methods: Charts of the children who underwent laparoscopic appendectomy due to appendicitis between March 11-September 30 between 2017-2020 were retrospectively analyzed in terms of demographic data, duration of symptoms, duration between hospital admission and surgery, radiologic imaging and perioperative outcomes.

Results: This study includes 467 children who underwent laparoscopic appendectomy. There were 97 procedures in 2020, 111 in 2019, 146 in 2018 and 113 in 2017. Multiple comparison tests revealed that age did not show difference; but onset of symptoms in admission (p= 0.004), hospitalization time before surgery (p< 0.001), total hospitalization time (p< 0.001) showed statistically significant difference between years. Pairwise comparisons showed that these parameters were increased in 2020 compared to other years. Perforated appendicitis rate was significantly increased in 2020 when compared to previous years.

Conclusion: Although there is no direct relation between appendicitis and COVID-19 infection in the current knowledge, perforated appendicitis was found to be increased in children during the COVID pandemic. Reason of the higher rate of perforated appendicitis may be multifactorial; however, the pandemic appears to have a role in increased morbidity in children with appendicitis indirectly due to delay of hospital admissions.

Keywords: Appendicitis, child, coronavirus, pandemic, pediatric surgery

INTRODUCTION

Appendicitis is a common surgical emergency among children (1). It may present as acute appendicitis (AA) or perforated appendicitis (PA). AA constitutes 1-8% of the cases among children admitted to the emergency department with complaints of abdominal pain (2). PA is not as common as AA, but it remains to contain majority of appendicitis cases in children under three years of age (1).

Widely accepted treatment of AA includes laparoscopic or open appendectomy, but recently studies on non-operative treatment with parenteral antibiotics have been documented (1,3). Non-operative treatment has not been established yet in PA except appendiceal plastron in which the peritoneal dissemination of intestinal content is limited by the omentum and intestines. Morbidity of PA is much higher than AA, as expected (4). It also has the risks of increased hospital stay, longer use of parenteral antibiotics, sepsis and even death (5).
As we all know, the coronavirus pandemic affected the system of hospitals more than any other field. Outpatient clinics nearly stopped for few months in our country as well as others, and all attention was canalized to emergency and infectious diseases. “Stay at home” policy was also valid for patients in the need of routine controls, and at some point, a great amount of people were concerned about visiting the hospitals for any reason even though the situation was urgent or necessary.

In these extraordinary conditions, we thought that PA rate might have increased due to multiple reasons such as delayed apply to hospital, immunocompromised status of the child, children’s tendency to hide the pain from their parents due to anxiety, experiencing difficulties of reaching healthcare, and etc. Even though we could not evaluate all these factors; the basic hypothesis of the study was that PA incidence might be higher in pandemic conditions when compared to the same periods of past years independently from patient age.

MATERIAL and METHODS

The study was performed in adherence to the latest version of Declaration of Helsinki, and ethics approval was obtained.

Dates

March 11, 2020 was accepted as the set point for the study as it was the day when the first case infected with coronavirus was publicized in Turkey. Charts of the children who underwent laparoscopic appendectomy due to appendicitis between March 11-September 30 were retrospectively analyzed for the years of 2017, 2018, 2019 and 2020.

Patients

Children who underwent LA were included in this study. Since the beginning of the pandemic, all children underwent COVID-19 PCR test, and they were questioned for contact with people infected with COVID-19 preoperatively. The COVID-19 PCR tests ensued in between 6-24 hours, and meanwhile intravenous antibiotic therapy was administered to the children while awaiting the PCR test results after diagnosis of appendicitis. Children with positive PCR test and suspicious contact of COVID-19 were managed conservatively and they were excluded from the study (n= 6). Children with additional diseases which may cause prolonged hospitalization were excluded. Incidental and interval appendectomies were also excluded.

Surgical Method

All children with a prediagnosis of appendicitis- PA or AA underwent LA with three ports in case of absence of suspicious contact of COVID-19 or COVID-19 PCR positivity.

Data

Demographic data of the children were recorded. Presence of appendiceal perforation was determined according to operation notes or histopathologic examination. Perforated appendicitis was defined as a visible hole on the appendix wall and/or fecaliths in the abdominal cavity during the surgery. A hole on the appendix wall in pathologic examination was also accepted perforated appendicitis. Hospitalization before surgery was defined as the period from hospital admission to surgery. Hospital stay was described as the period from surgery to discharge. PA rates were also recorded.

Evaluation: PA rates in the same periods of 2017 to 2019 were evaluated combinedly and separately for each year and compared to 2020.

Statistical Analysis

Before comparative analysis, continuous variables were evaluated for normal distribution by histogram graphs and Kolmogorov-Smirnov test. Variables (age, total hospitalization time, hospitalization before surgery) which did not have normal distribution were evaluated by the Kruskal-Wallis test, and normally distributed data were analyzed by Anova test in terms of the presence of difference between years. Post-hoc tests were performed to evaluate the difference between groups. Chi-Square test was conducted for association of years and diagnosis. p value <0.05 was considered statistically significant. Benferoni correction was used for multiple comparisons. Statistical Package for the Social Sciences (SPSS), version 16.0 (IBM®, Chicago, USA) was used for analysis.

RESULTS

This study included 467 children who underwent LA due to AA or PA. One hundred and seventy-four (37.3%) were females and 293 (62.7%) were males. Mean age of the children was 11.4 years (1-18 years). There were 97 LA procedures in 2020, 111 in 2019, 146 in 2018 and 113 in 2017. Mean onset of symptoms at admission was 29.5 hours (4 hours-14 days). Mean hospitalization time before surgery and total hospitalization time were 9.5 hours (1-24 hours) and 1.7 days (1-13 days), respectively. Multiple comparison tests revealed that ages of the children in each year were not different; but time between onset of the symptoms and hospital admission, hospitalization time before surgery and total hospitalization time showed statistically significant difference between the years (Table 1). Pairwise comparisons showed that these variables increased in 2020 compared to other years (Table 2). PA rate was significantly increased in 2020 compared to previous years (Table 3, Figure 1). PA diagnosis on ultrasound was concordant with intraoperative findings for 18 of 30 children for perforated appendicitis in 2020, 6/13 in 2019, 14/18 in 2018 and 5/13 in 2017, and no difference was found between years statistically (p=0.117) (Table 4).

DISCUSSION

First COVID-19 case was reported from China at the end of 2019, and the disease rapidly spread all around the world in few months and was declared as a pandemic by WHO in March 2020 (6). In Turkey, the first COVID-19 case was detected on March 11,
Increased perforated appendicitis rates in children during COVID-19 pandemic

2020 and increased by days (7). The disease affect children as well, but in contrary with adult population, they usually stay asymptomatic (8). Surveillance data from Turkey has revealed that 0.8% of children had severe disease (7). Despite Multisystem Inflammatory Syndrome (MISC) which was described in children after COVID-19 infection; they still seem to be less symptomatic and fatal comparing to adults (7,9).

Figure 1. Rates of acute and perforated appendicitis.
The primary outcome of the study was to find out whether PA rates increased in pediatric population during the COVID pandemic. With similar means of ages in children in the above-mentioned years, PA rates was found to be increased in 2020 compared to prior years. Onset of symptoms at admission, total hospitalization time, time before surgery were also higher in 2020.

Conventionally, perforation of the appendix is considered to occur within 24 to 36 hours after the onset of symptoms (10). PA consists approximately 20% of children with appendicitis aged 10-17 years, and it is more common in younger children (10). Delayed presentation is the most important factor leading PA, and PA rates increases linearly with duration of symptoms (9,11). In the present study, despite the fact that age of the patients, which is a risk factor for increased PA rates, was not different between years, PA rates were found significantly increased in 2020 compared to previous three years. Duration of symptoms in admission was higher than prior years (40 hours vs 26.6, 28.6, 24.6 in 2020, 2019, 2018, 2017, respectively, p= 0.04). Total hospitalization time was also increased in this period, as expected. In concordant to present study, Fisher et al. have reported that PA rates was increased during 10 weeks of outbreak which can reflect the acute period of pandemic, comparing to their earlier practice in New York City (9). Parents’ concerns of exposure to COVID-19 in hospital may lead to delay presentation of children with appendicitis. Even though COVID-19 cases have reduced, and limited normalization policies have been mentioned in Turkey, in the tenth month of pandemic, delayed apply to hospital seems to be an important problem that may have caused increased morbidity and prolonged hospitalization in children with appendicitis.

As a result of waiting for the COVID PCR test results for the operation, time before surgery was longer in 2020 compared to prior years. We evaluated duration of symptoms and ultrasound findings of children in admission for appendicitis suspicion to distinguish whether high PA rates arose from preoperative waiting time for PCR results or delayed apply. When the prediction rates of perforation via ultrasonography were analyzed for each operation, time before surgery was longer in 2020 compared to previous three years. Duration of symptoms in admission was higher than prior years (40 hours vs 26.6, 28.6, 24.6 in 2020, 2019, 2018, 2017, respectively, p= 0.04). Total hospitalization time was also increased in this period, as expected. In concordant to present study, Fisher et al. have reported that PA rates was increased during 10 weeks of outbreak which can reflect the acute period of pandemic, comparing to their earlier practice in New York City (9). Parents’ concerns of exposure to COVID-19 in hospital may lead to delay presentation of children with appendicitis. Even though COVID-19 cases have reduced, and limited normalization policies have been mentioned in Turkey, in the tenth month of pandemic, delayed apply to hospital seems to be an important problem that may have caused increased morbidity and prolonged hospitalization in children with appendicitis.

Comparison of sonographic evaluation with intraoperative perforation findings revealed that each year sonographic evaluation may miss some amount of PA. Excluding this waiting time duration lead uled correlate the increase in PA with delayed apply to the hospital. Mean time before surgery was 18.7 hours in 2020 and it was longer compared to years before the COVID-19 pandemic (7.6 hours, 6.7 hours, 7.2 hours in 2019, 2018, 2017 respectively, p< 0.001). Given the present data, it seems feasible and harmless to wait for confirmation of COVID-PCR negativity to prevent virus exposure to airway providers and surgical team during the airway management and surgery.

Clinical features of COVID-19 in children include fever and cough, gastrointestinal symptoms; however, most of the infected children appear to be asymptomatic (12). Furthermore, gastrointestinal manifestations may develop both in COVID-19 infection and appendicitis (9,10,12). It may also confuse the physicians in this unusual conditions. Thus, we strongly recommend to wait for PCR results in children planned to undergo appendectomy procedure.

Non-operative management was described for non-perforated appendicitis in children with a success rate of 58%-82 (13,14). Interval appendectomy and non-operative management have been discussed even in complicated appendicitis by some authors (15,16). Kvasnovsky et al. have reported experience of non-operative management for appendicitis with a success rate of 86% during the pandemic in New York City and they found no difference in length of hospital stay between children who were managed non-operatively and children who underwent surgery due to simple appendicitis (17). The safety of anesthesia in patients with positive PCR for COVID-19 is unclear, but early reports suggest a possible relation with increased perioperative complications (18,19). In case of proven or high risk of COVID-19 infection which is concomitant to appendicitis, we strongly recommend considering non-surgical treatment as an option for both; the child and the surgical team.

Retrospective nature of the study is one of the most significant limitations. Also, our clinical observation on increase of PA rates in this period may cause bias even though the analysis of the data was performed by two separate researchers who were blinded to the years. Although same months of the years were selected for elimination of seasonal variability of PA, usage of uncontrolled data from the hospital database may decrease the
Increased perforated appendicitis rates in children during COVID-19 pandemic

veracity of the data, and it was not possible to reach out all par-
tients and check the medical histories of children. Even though
the number of the patients was satisfactory, the analysis was
based on timing but not very detailed in other aspects. Thus,
it was not possible to evaluate other reasons that may have
played role in appendical perforation. Also, perforation predic-
tion rates were basically based on sonographic imaging which
may be classified as a subjective imaging method.

CONCLUSION

PA rates seem to be increased in pandemic conditions. In ad-
dition, duration of symptoms before hospital admission was
higher in this period. Hospital stays were longer due to waiting
for PCR tests, but it seems it did not increase PA rate much more
than previous years.

Ethics Committee Approval: This study approval was obtained from An-
kar University Human Researchs Ethical Committee (Decision No: 11-67-
21, Date: 28.01.2021).

ÖZET

Bulgular: Çalışmaya laparoskopik apendektomi uygulanan 467 çocuk hasta dahil edildi. 2020 yılında 97, 2019 yılında 11, 2018 yılında 146 ve 2017 yılında 113 cerrahi işlem mevcuttu. Çoklu karşılaştırma testleri yaşın farklılık göstermediğini ancak yıllar arasında istatistiksel olarak anlamli farklılıkların başvuruda bulguların başlangıcı (p=0,004), ameliyat öncesi hastanede yatış süresi (p<0,001) ve toplam hastanede yatış süresi p<0,001) değişkenlerinde olduğunu ortaya koydu. İkili karşılaştırmalar bu parametrelerin diğer yıllara oranla 2020 yılında arttığını gösterdi. Perfore apandisit oranı, diğer yıllara kıyasla yasaya 2020 yılında anlamlı derecede yüksek bulundu.
